Received July 14, 2014

Background & objectives: Chikungunya (CHIK) fever is a mosquito-borne disease caused by chikungunya virus (CHIKV). Chikungunya infection was first reported from India in 1963 from Kolkata. We report the serological and molecular evidence of an outbreak of chikungunya in northeast India that occurred in Tura, a hilly and forested terrain in Garo Hills district of Meghalaya.

Methods: Blood samples (3 ml) collected from hospitalized patients during the outbreak were tested for IgM antibodies against CHIKV and followed up four months later. A repeat survey was carried out in the same area after four months from where cases had been reported. Blood samples were also collected from people with history of fever and body ache in the last four months. Persons showing IgM positivity against CHIKV in the repeat survey were followed up one and a half years later. All samples were also processed by RT-PCR assay for CHIK Envelope (E) 1 gene. Immature mosquitoes were collected, link reared and identified with standard keys. Virus incrimination studies were done on Aedes aegypti and Ae. albopictus mosquitoes collected during the survey.

Results: Fever, headache and joint pain were the primary clinical presentations. Twenty three (35.93 %) of 64 samples reported during the outbreak were IgM positive for CHIK. Three samples showed PCR amplification. All these were IgM positive. The sequenced E1 gene revealed that the strains belonged to East Central South African (ECSA) genotype.

Interpretation & conclusions: Field survey done after four months revealed that some individuals still had joint pain associated with episodes of headache and fever. It could be inferred that these persons might have contracted infection during the CHIK outbreak four months ago or during the intervening period which caused persistence of sequelae. ECSA genotype was found to be involved in the outbreak. Aedes albopictus was the predominant mosquito species collected during the outbreak.

Key words Aedes albopictus - antibodies - CHIK - chikungunya - genotype - IgM - Meghalaya

Chikungunya (CHIK) is an arthropod-borne viral infection of public health importance. The disease was first reported during an outbreak in Southern Tanzania in 1952. Since then, this disease has been reported from parts of Africa, Asia and recently from some parts of Europe. CHIK has been reported in nearly 40 countries in the form of separate outbreaks. The clinical symptoms of CHIK include fever, joint pain, muscle pain, headache, nausea, fatigue and rash. The joint pain is often unbearable and usually lasts for a few
days to weeks. The causative organism, chikungunya virus (CHIKV), belongs to genus Alphavirus, family Togaviridae. CHIK transmission in humans is caused by Aedes (Stegomyia) aegypti (Linnaeus) and Aedes (Stegomyia) albopictus (Skuse) mosquito species.

CHIK was first reported from West Bengal State of India in 1963. Subsequently, a major outbreak occurred in Maharashtra in 1973 after which CHIK had disappeared till 2005. Afterwards, outbreaks occurred in Andhra Pradesh and Karnataka, spreading over to eight States of the country. In between, suspected CHIK cases have been reported from various parts of India. The first evidence of CHIKV infection among hospitalized patients in Assam, northeast India was reported in 2011. We report here the serological and molecular evidence of a CHIK outbreak in northeast India in a Garo tribe dominated Tura township of West Garo Hills district, Meghalaya.

**Material & Methods**

During November 2010, suspected cases of fever of unknown origin (FUO) were reported from Tura, West Garo Hills district of Meghalaya State, India. Clinical symptoms were suggestive of CHIKV infection. The case definition of suspected CHIKV infection was as per World Health Organization (WHO) guidelines viz. fever, arthralgia, headache and backache. A total of 64 patients suspected to have CHIKV infection were admitted to Tura Civil Hospital, Meghalaya during November 2010. All patients were from Tura township area. Serum samples from these patients were transported under cold conditions to the Regional Medical Research Centre (RMRC), Dibrugarh, Assam, for laboratory investigations. Outbreak investigation was conducted by us as per Indian Council of Medical Research (ICMR) guidelines of 10 steps for outbreak investigation during November 2010.

**Serological diagnosis:** All serum samples were tested for acute phase infection for immunoglobulin M (IgM) antibodies against CHIKV using IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA) kits supplied by the National Institute of Virology (NIV), Pune, India. Tests were carried out according to manufacturer’s instructions.

**Virus isolation and molecular detection of circulating CHIKV strains:** CHIKV isolation from 14 acute phase serum samples was attempted in one day old suckling Swiss albino mice. The mice were observed for 14 days for typical symptoms of sickness. All 64 serum samples were also screened for CHIK Envelope 1 gene by reverse transcription-polymerase chain reaction (RT-PCR) based on the protocol of Yergolkar et al., with some modifications. Viral RNA was extracted using QIAamp viral RNA mini kit (Qiagen, Germany). Complementary DNA (cDNA) was synthesised using cDNA synthesis kit (Fermentas, USA). The primers that amplified a 294 bp product of Envelope (E) 1 gene were CHIK/E1-S 5’ TAC CCA TTC ATG TGG GGC 3’ and CHIK/E1-C 5’ GCC TTT GTA CAC CAC GATT 3’. PCR amplicons were further outsourced to Eurofins Pvt. Ltd., Hyderabad, India, for sequencing. Both forward and reverse direction of each sequence were checked and edited manually using BioEdit Sequence Alignment Editor Software (BioEdit, California, USA). Edited sequences were submitted to NCBI GENBANK and respective accession numbers obtained.

**Field investigations and follow up:** Following laboratory confirmation of CHIK outbreak, a repeat field survey was undertaken after four months in April 2011 to assess the prevailing disease status. The CHIK positive cases were followed up and interviewed for sequelae. Blood samples (3 ml) were collected from other people in the neighbourhood who were complaining of joint pain associated with fever episodes. Following this, a second survey was done in January 2013 for the same patients after an interval of one and a half years. All samples were tested by IgM MAC ELISA kits (NIV, Pune). Long-term sequelae and other associated symptoms were recorded in a pre-tested and validated standard questionnaire developed by us. Ethical approval for carrying out the survey was obtained from RMRC, Dibrugarh Institutional Ethics Committee.

An entomological survey was undertaken by RMRC, Dibrugarh to identify the vector/s involved to plan vector control and disease containment strategies. As part of mosquito surveillance programme, solid waste containers, viz. bamboo stumps, metal and plastic wares, cans, flower pots, discarded automobile tyres, etc. holding water, as well as domestic water storage containers were searched for immature stages (larvae and pupae) of mosquitoes. Immature mosquitoes were link reared and on emergence to adults, were identified using standard mosquito identification keys.

**Statistical analysis:** Data were described by time, place and person by using frequency distribution of clinical symptoms, age group and gender, period of illness as well as spatial distribution of cases in the outbreak areas. Percentage frequency of clinical symptoms,
epidemic curve values and attack rates were calculated by using SPSS 13 software (SPSS, Inc., Chicago, USA). The analysis was done by comparing suspected versus laboratory confirmed cases. The categorical data were analysed using chi-square test and difference in continuous data by independent t test. The container preference of *Aedes* larvae was assessed by calculating breeding preference ratio\textsuperscript{16}.

**Results**

A total of 64 patients from Tura township area were admitted to the Tura Civil Hospital during November, 2010. Of the 64 samples collected from the hospitalized patients, 23 (35.93%) were IgM ELISA positive. The common clinical presentations were fever (70%), body ache (39.13%), joint pain (30.43%) and headache (26.1%). Male patients comprised 57 per cent (n=36) of positive cases. The positive patients were from all age groups (range 12- 65 yr) with a median age of 32 yr. However, no significant association was noticed with age or gender. The distribution of CHIK cases over time gave a step ladder pattern epidemic curve (Figure). The positive cases were concentrated in four areas- Nakham Bazar, Lower Hawakhana, Rishipara and Tura Bus stand of the Tura Township which had a population of about 18000. The attack rates of CHIK cases showed that males (0.14%) suffered more than females (0.11%). The attack rate of affected population was 0.13 per cent.

**CHIKV isolation and molecular typing of circulating CHIKV isolates:** No CHIKV isolate was obtained in the present study. PCR amplification was detected in 3 of 64 samples. The sequences were submitted to NCBI GENBANK (Gen Bank accession no. KF985235.1, KM058063 and KF840729.1) All three strains were placed within East Central South African (ECSA) genotype.

**Human epidemiology and vector surveillance investigations:** Ten of 23 positive cases (43%) could be traced during a repeat follow up after four months of the outbreak. Persistence of joint pain was reported in all these cases. At this point of time, 110 blood samples from persons complaining of past or persisting episodes of fever and body ache from the surrounding areas of the CHIK cases were also collected. Of these, 24 (21.81%) were found positive for CHIK IgM antibodies. These cases were followed up after one and a half years to investigate long-term sequelae and persistence of IgM antibodies. Eleven of the 24 CHIK IgM positive cases could be traced at follow up (46%). None complained of any sequelae.

During the entomological survey *Ae. albopictus* and *Ae. aegypti* mosquitoes were found both in immature as well as adult collections. The most common habitats for *Aedes* breeding were discarded automobile tyres, mostly stored in the open in tyre repairing shops and huge solid waste scrape dump yards in the vicinity of the bus stand and market area of Tura.

Discussion

This study reports the first CHIK outbreak in Northeast India that occurred in the State of Meghalaya in a Garo hill tribe dominated Tura Township in West Garo Hill district in 2010. The detection of IgM antibodies specific for CHIKV in acute-phase serum specimens was considered to be confirmatory. Diagnosis of CHIK was based on two important signs in acute phase: fever and arthralgia having a specificity of 99.6 per cent and positive predictive value of 84.6 per cent. The typical feature of CHIK includes severe joint pain in almost all cases. Similar presentation was observed in our study. Most infections completely resolve within weeks or months but there are reports of CHIK fever-induced arthralgia persisting for several years. Persistence of CHIK typical clinical presentations - fever and arthralgia were noticed in 40 per cent positive cases after four months of infection.

The positive cases were clustered in four areas - Nakham Bazar, Lower Hawakhana, Rishipara and Tura Bus stand of Tura Township. Majority of people residing in these areas were non tribals. Epidemic curve with a step ladder pattern indicated a mosquito borne disease with an extrinsic and intrinsic period involving 10-19 days. Tyres, water collection plates beneath flower pots, fencing bamboo stumps, reservoirs and uncovered water storage containers in addition to extensive solid waste dump yards were identified as major breeding habitats for the Aedes vector species in the affected areas. Subsequently, information, education and communication (IEC) activities combined with massive malathion fogging and Aedes breeding habitat elimination drives in the affected and adjoining areas were initiated by the Meghalaya State Health machinery that helped in checking any further spread of the disease within a span of 40 days. No new case was reported beyond November 28, 2010. During our field survey four months post outbreak, 110 people from the same locality complained of suffering from joint pain associated with fever episodes during the last four months. Twenty four of them were found to be CHIK IgM positive. These cases would probably have contacted the CHIKV infection during the outbreak and CHIK IgM is known to persist for as long as 22 months. These positive cases were followed up after 18 months. However, no significant residual clinical presentations or sequelae were observed.

The partial E1 gene sequences demonstrated that all three CHIKV strains from Meghalaya belonged to ECSA genotype. There are three distinct genotypes of CHIKV: Asian, ECSA and Western African. The ECSA genotype has been the dominant strain throughout Asia and the islands and countries in the Indian Ocean over the last decade. CHIKV is spread by both Aedes aegypti and Aedes albopictus species. However, in a separate study carried in Malaysia, it was observed that ECSA genotype infected Aedes albopictus at a higher rate than Aedes aegypti. The BI threshold for predicting CHIK transmission in India is not available. However, BI higher than 5 is the threshold for dengue transmission. It has been reported that ECSA genotype has replaced the earlier circulating Asian genotype in parts of India. Identification of chikungunya virus ECSA genotype in the present outbreak is in conformity to the above observation.

The persistence of CHIKV and regular occurrence of outbreaks in south Asia is a major cause of concern. The Northeastern region of India shares international borders with Bangladesh, Bhutan, China, Myanmar and Nepal. Of these, Bangladesh lies at close proximity with Tura, Meghalaya. CHIK outbreaks were reported from Bangladesh in 2008 (Rajshahi district), 2009 (Pabna district) and 2010. The Tura outbreak occurred in 2010, further followed by CHIK outbreaks in Bangladesh in Chapainababganj and Dhaka districts in 2012 and again in Dhaka in 2013. However, no other CHIK outbreak has been reported from anywhere in Northeast India since 2010 till date. The region has been recognized as one of the hot spots of biodiversity in the world and a high prevalence of Aedes species mosquitoes throughout the entire Northeast India has been reported. This poses a threat of occurrence of CHIK in newer areas in future. Thus, public awareness activities combined with efforts to eliminate the identified risk factors for Aedes species need to be undertaken to prevent any chikungunya outbreak in this region in future.
